Abstract. Vertical distributions of aerosol optical properties derived from measurements made during 11 aircraft flights over the North China Plain (NCP) in May–June 2016 during the Air Chemistry Research In Asia (ARIAs) were analyzed. Aerosol optical data from in situ aircraft measurements show good correlation with ground-based measurements. The regional variability of aerosol optical profiles such as aerosol scattering and backscattering, absorption, extinction, single scattering albedo (SSA), and the Ångström exponent (α) are thoroughly characterized for the first time over the NCP. The SSA at 550 nm showed a regional mean value of 0.85 ± 0.02 with moderate to strong absorption and the α ranged from 0.49 to 2.53 (median 1.53), indicating both mineral dust and accumulation-mode aerosols. Most of the aerosol particles were located in the lowest 2 km of the atmosphere. We describe three typical planetary boundary layer (PBL) scenarios and associated transport pathways as well as the correlation between aerosol scattering coefficients and relative humidity (RH). Aerosol scattering coefficients decreased slowly with height in the clean PBL condition, but decreased sharply above the PBL under polluted conditions, which showed a strong correlation ($R^2 \geq 0.78$) with ambient RH. Back-trajectory analysis shows that clean air masses generally originated from the distant northwestern part of

China, while most of the polluted air masses were from the heavily polluted interior and coastal areas near the campaign region.

1 Introduction

Aerosol loading in eastern China has become exceptionally heavy and highly variable due to drastic increases in the emissions of pollutants during the last several decades. Changes in air quality and climate are strongly coupled (Li et al., 2016), and both have tremendous impacts on the public health of the densely populated region (Kan et al., 2012).

Aerosol particles are considered to be an important radiative forcing agent in the climate system, but the detailed effects remain uncertain (Stocker et al., 2013). Aerosols modify the local and regional radiation budget and climate by absorbing and scattering solar radiation through the aerosol direct effect (Charlson and Hofmann, 1992) and impact photochemistry (Dickerson et al., 1997). Aerosols can also affect cloud–precipitation processes and aerosol–cryosphere interactions through indirect and semi-direct effects (Twomey, 1974; Lohmann and Feichter, 2005; Andreae and Rosenfeld, 2008; Nair et al., 2013). Several recent studies have shown

that the magnitude of precipitation is strongly correlated to aerosol concentration (Zhao et al., 2006; Li et al., 2011; Tao et al., 2012), through various mechanisms as summarized most recently in Li et al. (2017b). Precipitation frequency and intensity are also altered by the long-term impacts of aerosols (Guo et al., 2016, 2017). Much of the uncertainty in aerosol radiative forcing comes from the variability of optical properties in anthropogenic aerosol such as scattering, absorption, backscatter, Ångström exponent (α), and aerosol optical depth (AOD). These properties depend strongly on particle size distribution, chemical composition, and the ambient relative humidity (Anderson et al., 2003). The spatial and temporal variations of these properties, especially horizontal and vertical distributions, are essential factors in the effects of aerosols on both climate and the environment (Haywood and Boucher, 2000).

Aerosol scattering and absorption coefficients (σ_{sca} and σ_{abs} , respectively) are important parameters related to atmospheric characteristics such as visibility and air quality. Observed σ_{sca} and σ_{abs} are generally distinct within versus above the planetary boundary layer (PBL). The structure of the PBL, in part determined by the vertical distribution of the aerosol extinction coefficient (σ_{ext} , the sum of σ_{sca} and σ_{abs}), is a crucial factor in estimating aerosol pollution conditions (Yu et al., 2002; Dong et al., 2017), partially due to their strong interactions/coupling (Li et al., 2017a). Given the variability of PBL structure and its interaction with aerosols, the transport of pollutants is yet to be fully understood. Distinguishing between local air pollutants and pollutants transported from other source regions and identification of transport patterns under different atmospheric circulation conditions also need to be addressed. Dust aerosols can be lifted into the free troposphere, i.e., above the PBL, and transported over a long distance, altering aerosol vertical distributions over remote areas (Han et al., 2008). Topographically generated local circulations can carry high concentrations of surface air pollutants and change the PBL structure (Chen et al., 2009). Such variable aerosol vertical distributions can alter the optical properties of aerosols such as AOD, thus affecting the regional radiation balance (Liu et al., 2012) and even the global radiative forcing estimation (Zhang et al., 2013). A number of field programs have been carried out to measure the vertical distribution of dust or biomass burning aerosols with airborne and surface-based instruments (Johnson et al., 2008). The observations, combined with a radiative transfer model, allow the accurate calculation of radiative effects including aerosol optical properties (Gadhavi and Jayaraman, 2006) and absorption of solar radiation at the top of the atmosphere (Meloni et al., 2005).

Three-dimensional information about aerosol optical properties (especially vertical distributions) is of importance, but such measurements are scant (Kahn et al., 2017). Given the potential impact of aerosols on climate, additional accurate measurements of the vertical profiles of aerosol optical properties are needed. These data can be obtained directly

or indirectly from platforms such as meteorological towers (Zhao et al., 2017), tethered balloons (Stratmann et al., 2003; Ferrero et al., 2010), and unmanned aerial vehicles (Corrigan et al., 2008). Although limited in terms of temporal and geographic coverage, airborne sensing provides direct, high-resolution, in situ aerosol vertical profiles, used to evaluate numerical models and satellite retrievals (Chazette and Liousse, 2001).

Airborne instruments have been used to characterize aerosol properties in the lower troposphere around the world (Wandinger et al., 2002; Haywood et al., 2003a; Taubman et al., 2004, 2006; Hains et al., 2008; Ferrero et al., 2011; Ryder et al., 2013; Kim et al., 2015; Schwarz et al., 2016; Babu et al., 2016), as well as in China, e.g., in Beijing (Zhang et al., 2006, 2009, 2011; Liu et al., 2009), Dongbei (Dickerson et al., 2007), Hebei (Sun et al., 2013), and Shanxi (Li et al., 2015a, b). Most of the measurements were made for parameters such as aerosol number concentration or size distribution.

In May–June 2016, a comprehensive joint ground and airborne experiment was conducted in the North China Plain (NCP). The study described here aimed to examine the consistency of airborne and surface-based measurements and to evaluate aerosol radiative characteristics and the distribution and transport of air pollutants both horizontally and vertically. It is an integral part of, also a foundation for, a series of studies on aerosol–cloud–climate interactions in a densely populated and rapidly developing region of China (Li et al., 2017a).

A twin-engine, turboprop airplane was deployed to measure trace gases and aerosol optical properties in the lower atmosphere, in coordination with ground-based in situ and remote measurements at the Xingtai supersite. The airplane flew ascents and descents in the boundary layer and the lower free troposphere to obtain vertical profiles of aerosol optical properties. High-resolution aircraft measurements of aerosol optical properties give detailed information about the occurrence, extent, and evolution of aerosol vertical distributions. Aerosol optical properties such as σ_{sca} and σ_{abs} , backscattering, extinction, single scattering albedo (SSA), α , and AOD from the airborne measurements are presented and discussed.

Details about the field experiment and the instruments used are given in Sect. 2. The vertical and regional distributions of aerosol optical properties are presented in Sect. 3. In Sect. 4, the structure of the PBL under both clean and polluted conditions, the correlation between vertical σ_{sca} and relative humidity (RH), and back-trajectory analyses are discussed. Section 5 summarizes the major conclusions from this study.

2 Experimental description

2.1 Sites and flight information

The Aerosol Atmosphere Boundary-Layer Cloud (A²BC) campaign took place in Hebei Province of the NCP, about 300 km south of Beijing, from May to December 2016. An intensive observation period (IOP) was from May to June when airborne observations were conducted using two airplanes to measure aerosol and cloud properties, respectively. A supersite was established in Xingtai (XT; 114.36° E, 37.18° N; 182 m above sea level, or a.s.l.). The National Science Foundation supported the project “Air chemistry Research In Asia” (ARIAs), with the goal of integrating in situ observations, satellite remote sensing, and chemical transport models to characterize and quantify tropospheric chemistry and composition over the NCP and to improve modeling tools used to eventually evaluate the effectiveness of air pollutant reduction policies. NASA’s Korean US Air Quality (KORUS-AQ) experiment was conducted at roughly the same time in the downwind region. One of the airplanes (Y-12), which was based at Luancheng Airport (LC; 114.59° E, 37.91° N; 58 m a.s.l.), located in the southeast of Shijiazhuang, the capital of Hebei Province, measured aerosol properties. The airplane was flown to three locations in the area to conduct spirals from ~300 to ~3.5 km, as shown in Fig. 1. These locations include XT, Julu (JL; 115.02° E, 37.22° N; 30 m a.s.l.), and Quzhou (QZ; 114.96° E, 36.76° N; 40 m a.s.l.). All four sites are located to the east of the Taihang Mountains, with XT right at the foothill of the mountain range. A total of 11 flights were conducted during the A²BC and ARIAs IOP (Table 1).

Comprehensive measurements of aerosol optical properties were made during the field campaign using the instrumented turboprop Y-12 airplane operated by the Weather Modification Office of Hebei Meteorological Bureau. The typical speed of the aircraft is 60–70 m s⁻¹, with ascent/descent rates of 2–5 m s⁻¹. The aircraft was equipped with multiple aerosol and gas measurement instruments, and was rigorously tested and calibrated during a ground-based

campaign to optimize instrument performance. Table 2 summarizes the instruments deployed on the plane and ground.

2.2 Aircraft instruments

2.2.1 Nephelometer

Measurements of σ_{sca} from the Y-12 aircraft were made using an integrating nephelometer (TSI, model 3565) at three wavelengths: blue (450 nm), green (550 nm), and red (700 nm). Details about the instrument calibration and uncertainties have been described elsewhere (Anderson and Ogren, 1998; Anderson et al., 2009). The nephelometer was calibrated prior to the field campaign using CO₂ gas and filtered zero air as described in the instrument manual. It aspirates air at a flow rate of 30 L min⁻¹ through a forward-facing air inlet. Data were recorded at a frequency of 1 Hz.

The conical double diffuser aerosol inlet, designed for a Twin Otter, was installed on the Y-12. This inlet system was manufactured by Droplet Measurements Technologies (MP-1806-A and MP-1807-A, Boulder, CO, USA) (Hegg et al., 2005). It has been used extensively on the University of Maryland’s Cessna 402 (Brent et al., 2015). The passing ef-

Table 2. Instruments used in this study.

	Instrument	Parameter used in this study	Frequency	Accuracy
Airborne platform	Nephelometer, TSI Model 3565, USA	$\sigma_{\text{sca}}, \sigma_{\text{bsca}}$	1 s	0.5 Mm^{-1}
	PSAP, Radiance Research Inc., USA	σ_{abs}	60 s	0.1 Mm^{-1}
	CWIP, Rain Dynamics, USA	T	1 s	$\pm 1^\circ$
		RH	1 s	2 %
		Position	0.1 s	
Xingtai supersite	CAPS, Aerodyne Res. Inc., USA	σ_{ext}	1 s	$< 2 \text{ Mm}^{-1}$
	Radiosondes, Graw Model DFM-09, Germany	Pressure	1 s	0.1 hPa
		T		0.1°
		RH		1 %
	CIMEL, CE-318, France	SSA	Hourly	0.03

efficiency is expected to be near 100 % for particle diameters up to $2.5 \mu\text{m}$ and near 50 % for particles between 3 and $4 \mu\text{m}$ (Huebert et al., 2004; McNaughton et al., 2007).

The actual range of total scattering angles captured by the nephelometer is less than the ideal range of 0 to 180° . To correct the biases, we adjusted them with empirically derived angular truncation correction factors using the calculated α (Anderson and Ogren, 1998). To account for the hygroscopic growth of aerosols, the scattering values were adjusted using a correction factor $f(\text{RH})$ (Anderson et al., 2003; Shinozuka et al., 2007), calculated as

$$f(\text{RH}) = \left[\frac{(100 - \text{RH}_{\text{neph}})}{(100 - \text{RH}_{\text{amb}})} \right]^\gamma, \quad (1)$$

$$\sigma_{\text{sca_adj}} = \sigma_{\text{sca}} \times C \times f(\text{RH}), \quad (2)$$

where RH_{neph} is the internal nephelometer RH, RH_{amb} is the ambient RH, γ is an experimentally determined dry versus humid factor of the hygroscopicity (Beyersdorf et al., 2016), $\sigma_{\text{sca_adj}}$ is the adjusted scattering coefficient, σ_{sca} is the measured scattering coefficient, and C is the angular truncation factor. During the study period, the relative uncertainty after calibration was around a few percent (evaluated from the reproducibility of laboratory measurements).

2.2.2 PSAP

A particle soot absorption photometer (PSAP, Radiance Research, 565 nm) provides highly sensitive absorption measurements without interference by scattering signals. Its observation principle and uncertainties have been well documented (Bond et al., 1999; Sheridan et al., 2005; Virkkula et al., 2005; Chaudhry et al., 2007). To ensure a steady sample flow during flights, we monitored the total flow and PSAP flow rates to enhance the accuracy of measurements. The instrument operates at a flow rate of 2 L min^{-1} when 1 min measurement averages are used. The raw absorption coefficients from the PSAP, $\sigma_{\text{abs}, \lambda=565 \text{ nm}}$, were corrected to

550 nm using Eq. (3):

$$\sigma_{\text{abs}, \lambda_i} = \sigma_{\text{abs}, \lambda=565 \text{ nm}} \times \frac{565}{\lambda_i}, \quad (3)$$

where λ_i is the i th wavelength. Ideally, for this calculation, the absorption coefficient would also be measured under ambient conditions, but it is somewhat less dependent on humidification than scattering is (Schafer et al., 2014). Therefore, such calibrated measurement was not done during the field campaign.

2.2.3 Meteorological instruments

A cloud water inertial probe (CWIP, Rain Dynamics) measuring pressure, temperature (T), and RH was installed on the Y-12 aircraft. It was calibrated prior to the deployment and synchronized with the global positioning system (GPS) time and geolocation of the scientific data, dually calibrated by the GPS and the compass navigation satellite system (CNSS).

2.3 Instrumentation at the Xingtai supersite

A full suite of instruments to measure aerosol and meteorological parameters was deployed at the Xingtai surface supersite. Those of concern to this study include aerosol optical remote sensing observations (CIMEL radiometer), in situ particle light extinction measurements (cavity attenuated phase shift spectroscopy (CAPS) particle light extinction monitor), and radiosondes for meteorological parameters.

2.3.1 CAPS

We present field measurements of the ambient aerosol extinction coefficient (σ_{ext}) by using a CAPS instrument with a time resolution of 1 s at the Xingtai supersite. This technique has advantages such as high sensitivity, cost efficiency, easy control, and a long effective absorption optical path. The CAPS instrument measures the phase shift of a distorted

waveform of the modulated light from a light emitting diode (LED) in a sample cell with two high reflectivity mirrors (Sun et al., 2014). It has a demonstrated sensitivity of less than 2 Mm^{-1} for 1 s sampling periods. A method description, including results from laboratory characterization and field deployment, has been reported previously (Massoli et al., 2010). The CAPS extinction and the σ_{ext} measured by the combination of the nephelometer and the PSAP showed a good correlation in both laboratory-generated test particles and ambient aerosols (Petzold et al., 2013). The detailed principles of the CAPS technology, optical path adjustment process, and calibration method can be found in previous studies (Kebabian et al., 2008; Kebabian and Freedman, 2007).

2.3.2 Radiosondes

For comparisons with airborne measurements, radiosondes (Model DFM-09, Graw Radiosonde GmbH & Co. KG, Germany) were launched from the Xingtai supersite during the IOP. The DFM-09 radiosonde is a lightweight weather radiosonde that measures temperature (at a resolution of $0.1 \text{ }^\circ\text{C}$ with an accuracy of $0.2 \text{ }^\circ\text{C}$), pressure (at a resolution of 0.1 hPa with an accuracy of 0.5 hPa), RH (at a resolution of 1% with an accuracy of 2%), and wind speed (accuracy = 0.2 m s^{-1}) (Navas-Guzmán et al., 2014). RH is measured by a thin-film capacitance sensor, and its uncertainties and errors depend on temperature and GPS location (Steinke et al., 2015). Data acquisition and processing were performed at the Graw ground station located at the Xingtai supersite using the Grawmet software.

2.3.3 CIMEL automatic Sun–sky radiometer

To obtain an optical characterization of aerosol vertical distribution and to complement airborne measurements, we deployed a CIMEL sun photometer, the standard instrument used in the Aerosol Robotic Network (AERONET). The CIMEL (CE-318) used at the Xingtai AERONET site is a two-detector eight-channel (340, 380, 440, 500, 675, 870, 940, and 1020 nm) radiometer designed to make, automatically track, and measure direct solar and sky radiances with a field of view of approximately 1.2° . AOD and SSA are computed at each wavelength except the 940 nm channel, used to retrieve total column water vapor. The measurement uncertainty for field instruments, primarily due to calibration uncertainty, is spectrally dependent, with higher errors in the UV (Eck et al., 1999). The details of the CIMEL radiometer operating principles and network are described by Holben et al. (1998).

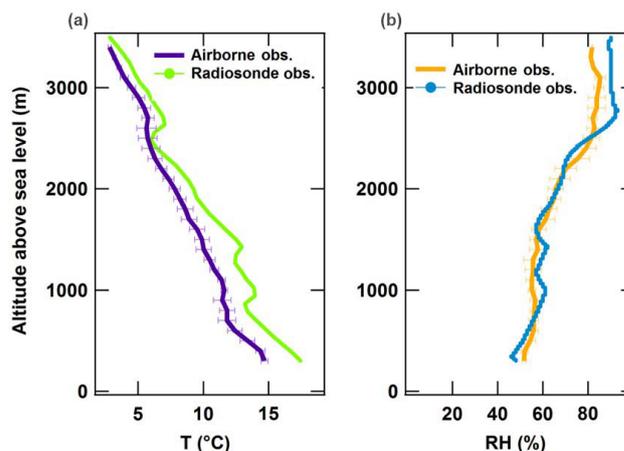

Figure 2. Vertical profiles of temperature (T , a) and relative humidity (RH, b) from radiosonde and airborne measurements made on 8 May 2016 over the Xingtai supersite. Horizontal bars represented standard deviations.

3 Vertical and regional distributions of aerosol optical properties

3.1 Comparison between aircraft and ground-based measurements

Ground-based measurements collected at XT were matched in time and space with airborne measurements over the site. Figure 2 shows the vertical profiles of RH and T from the sounding done at 05:55 coordinated universal time (UTC, 13:55 local time) on 8 May 2016 and from aircraft measurements made over the site before the radiosonde launch (04:40–05:40 UTC, one descent spiral and two ascent spirals). Both RH and T derived from sounding data and measured from the aircraft follow the same general trends, with inversions near 800 and 2400 m.

For a final evaluation of the performance of the airborne instruments in measuring ambient aerosol characteristics, the σ_{ext} measured by the nephelometer/PSAP on board the aircraft and by the ground-based CAPS PM_{ex} during research flight (RF) 6 (RF6; 21 May), RF7 (28 May), RF8 (28 May), and RF11 (11 June) is shown in Fig. 3. CAPS-measured σ_{ext} collected during the spiralling part of the flight was averaged and all σ_{ext} data were adjusted to a wavelength of 550 nm. In general, mean values of surface σ_{ext} were consistent with ($\sim 12 \%$ smaller than) the corresponding aircraft-measured σ_{ext} located at the bottom of the profiles.

There is an expected comparability of retrieval parameters (e.g., SSA) between ground-based observations and aircraft measurements. For example, the SSA values, derived from AERONET in Baltimore–Washington, DC, United States, were on average 0.011 lower than the values derived from aircraft profile measurements (Schafer et al., 2014). For aircraft–AERONET (based on the nephelometer combined with the PSAP, also used in this study) comparisons with

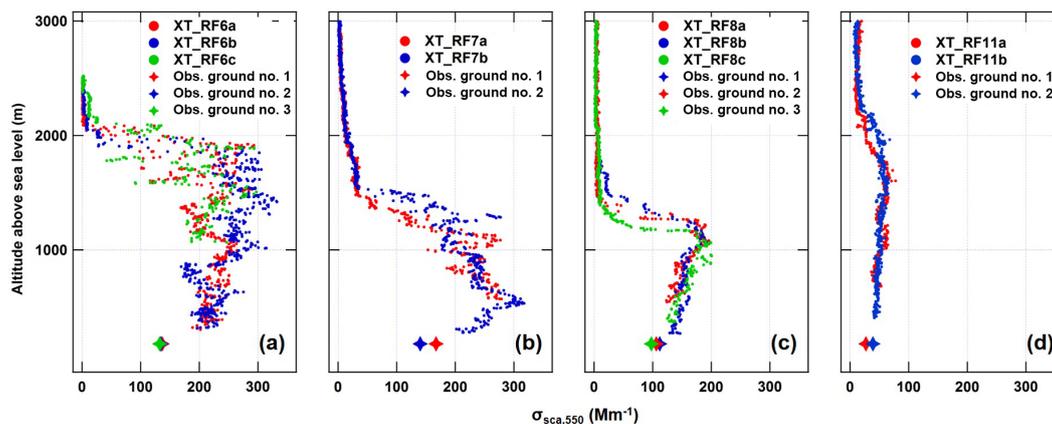

Figure 3. Aircraft-measured vertical profiles (colored circles) and surface CAPS-measured (colored plus symbols) σ_{ext} at 550 nm on (a) 21 May (RF6, panels a, b, and c represent spiral up/down), (b) 28 May (RF7), (c) 28 May (RF8), and (d) 11 June (RF11).

ground-based AERONET at multiple sites over southern Africa, the SSA with a mean difference of 0.01 (rms: 0.03) in biomass burning aerosol measurements (Leahy et al., 2007). There is also a small difference between aircraft in situ (0.87) and CIMEL (0.85) measurements of SSA on a day with both an upper-level smoke aerosol layer and low-level dust layer in the Banizoumbou (Johnson et al., 2010). For this study, retrievals from a ground-based CIMEL automatic Sun-sky radiometer (CE-318) were compared with aircraft in situ measurements.

We calculated the columnar SSA from airborne measurements and its uncertainties following Leahy et al. (2007) and Schafer et al. (2014). The sampled SSA (ω_{sample}) was calculated from σ_{sca} and σ_{abs} measured by a nephelometer and a PSAP, respectively. We assumed that in situ SSA measured between the minimum and maximum flight levels represents the entire column. In order to produce a column mean SSA (ω_{column}) and compare it with that retrieved from AERONET data, the SSA values were averaged for the duration of the profile after weighting the values according to aerosol loading. The columnar SSA was calculated with the same method for different types of aerosol layers in the vertical. Considering the vertical distributions of σ_{sca} and σ_{abs} , the SSA measured at higher altitudes (lower aerosol loading) is substantially lower than in the lower troposphere or the aerosol enrichment layer. Thus, the weighted mean is better than a simple average of ω_{sample} , which would overestimate the absorption features of aerosol that has a negligible effect on radiation at the surface where the CIMEL radiometer is located.

Aerosol loading, denoted by σ_{sca} values, and the profiles were limited to samples collected at the lower level below 400 m and at the higher level greater than 2000 m to adequately represent the entire column. For every profile, weighting factors for each SSA measurement were generated that corresponded to the normalized magnitude of σ_{sca} . The measured SSA values were scaled proportionally to the aerosol loading at the altitude of the observation as in the

following equation:

$$\omega_{\text{column}} = \frac{\sum_{i=0}^N \left[\frac{\sigma_{\text{sca}}}{\sigma_{\text{sca}(\text{profile_mean})} * \omega_{\text{sample}}} \right]}{N}, \quad (4)$$

where N equals the number of ω_{sample} in the profile.

The SSA at 550 nm retrieved from the CIMEL (0.93) agreed well with airborne measurements (0.94) on 28 May (Table 3). The well-matched vertical profiles and ground-based data present a more complete profile of aerosol optical information in the lower atmosphere, demonstrating the high credibility and quality of airborne measurements. These SSA values obtained in the NCP are lower than those observed in Africa, and in the northeastern United States. The reason for the difference is probably due to different types of aerosols in these different locations: primarily mineral dust aerosols in Africa and secondary aerosols in the northeastern United States, and a mix of these two types of aerosols in the NCP.

3.2 Statistics of aerosol optical properties

A statistical summary of aerosol optical properties retrieved from aircraft measurements over the four target areas (LC, JL, QZ, and XT) is given in Table 4. Aerosol scattering coefficients (σ_{sca}) and backscattering coefficients (σ_{bsca}) are directly obtained from the nephelometer. The truncation correction was applied and the σ_{sca} values were corrected for the ambient RH. The mean σ_{sca} values at 550 nm measured at LC, JL, QZ, and XT were 57.10 ± 67.71 , 95.57 ± 106.61 , 87.00 ± 100.43 , and $75.30 \pm 84.58 \text{ Mm}^{-1}$, respectively, and the mean σ_{bsca} value in each target area was 7.67 ± 7.6 , 9.91 ± 9.19 , 11.12 ± 10.51 , and $9.21 \pm 8.6 \text{ Mm}^{-1}$, respectively. Aerosol absorption properties at LC and XT were stronger than those at JL and QZ. Note that each variable has a large standard deviation, and there were large variations associated with these aerosol optical properties.

Mean vertical distributions of σ_{sca} and σ_{abs} at 550 nm derived from aircraft measurements made over the four target

areas are shown in rows 3 and 4 of Fig. 4. In general, the values of σ_{sca} and σ_{abs} decrease with altitude. Peaks in the σ_{sca} profiles at certain heights are seen at JL, QZ, and XT. The σ_{sca} profile at LC changes little below 3000 m. Compared with the other target areas, σ_{abs} values at JL are relatively lower near the ground and gradually decrease with height, which suggests that there were fewer light-absorbing and more scattering aerosols in this area.

Based on measurements of aerosol scattering and absorption coefficients, the aerosol extinction coefficient (σ_{ext} , defined as the sum of σ_{sca} and σ_{abs}) and SSA (ω , defined as the ratio of σ_{sca} to σ_{ext}) was calculated at 550 nm following Eq. (5):

$$\omega_{\lambda} = \frac{\sigma_{\text{sca},\lambda}}{\sigma_{\text{ext},\lambda}} = \frac{\sigma_{\text{sca},\lambda}}{\sigma_{\text{sca},\lambda} + \sigma_{\text{abs},\lambda}}. \quad (5)$$

The small mismatch in calculating ω was corrected by linearly extrapolating the σ_{abs} values to the wavelengths of the scattering measurements as defined. Both σ_{ext} and ω are considered to be primary determinants for the direct radiative effect of aerosols. The vertical profile of σ_{ext} closely follows that of aerosol mass concentration (Kim et al., 2015). SSA was described as an important factor in controlling whether an aerosol layer has a cooling or warming effect; it can also be used for studying the radiative forcing at the top of the atmosphere (Bergstrom and Russell, 1999). In this study, the ω_{550} in the range 0.68–0.99 with a mean value of 0.85 indicates the importance of absorbing aerosols.

The α was calculated using Eq. (6) where $\sigma_{\text{sca},\lambda}$ is the scattering coefficient at a given reference wavelength λ :

$$\alpha(\lambda_2/\lambda_1) = \frac{-\log(\sigma_{\text{sca},\lambda_2}/\sigma_{\text{sca},\lambda_1})}{\log(\lambda_2/\lambda_1)}. \quad (6)$$

In this study, we used two wavelengths, $\lambda_1 = 450$ nm and $\lambda_2 = 700$ nm.

An analogous expression can be written for the wavelength dependence of absorption. In general, α is a basic measure of the aerosol size distribution. It is related to the ratio of fine to coarse particles, with α less than 1 for coarse-mode aerosol such as dust particles and $\alpha \sim 2.0$ for very fine-mode aerosol such as smoke particles (Hamonou et al., 1999). Vertical profiles of the median values of ω_{550} and α are shown in rows 5 and 6 of Fig. 4. The profiles were generated by calculating the median value at each altitude layer from all the measured profiles. The variations seen may reflect changes in the origin of aerosol particles and transport routes (Léon et al., 2009), although the values fall well within the range of the standard deviations.

Angular-corrected data from the nephelometer is the scattered light intensity in the backward hemisphere of the particle (90–180°). The backscattering fraction, β_{sca} , is the ratio of the backscattering coefficient over the total scattering coefficient at a given wavelength (Garland et al., 2009). The ratio of forward scattering to backscattering varies with the particle size parameter and reflects the angular characteristics of particle scattering and the proportion of fine particles (diameters $< 2 \mu\text{m}$). During the field campaign, β_{sca} remained at low values below 2000 m. Mean values of β_{sca} measured in the four target areas were 0.13 ± 0.003 , 0.11 ± 0.005 , 0.12 ± 0.003 , and 0.12 ± 0.006 . Fluctuations above 2000 m

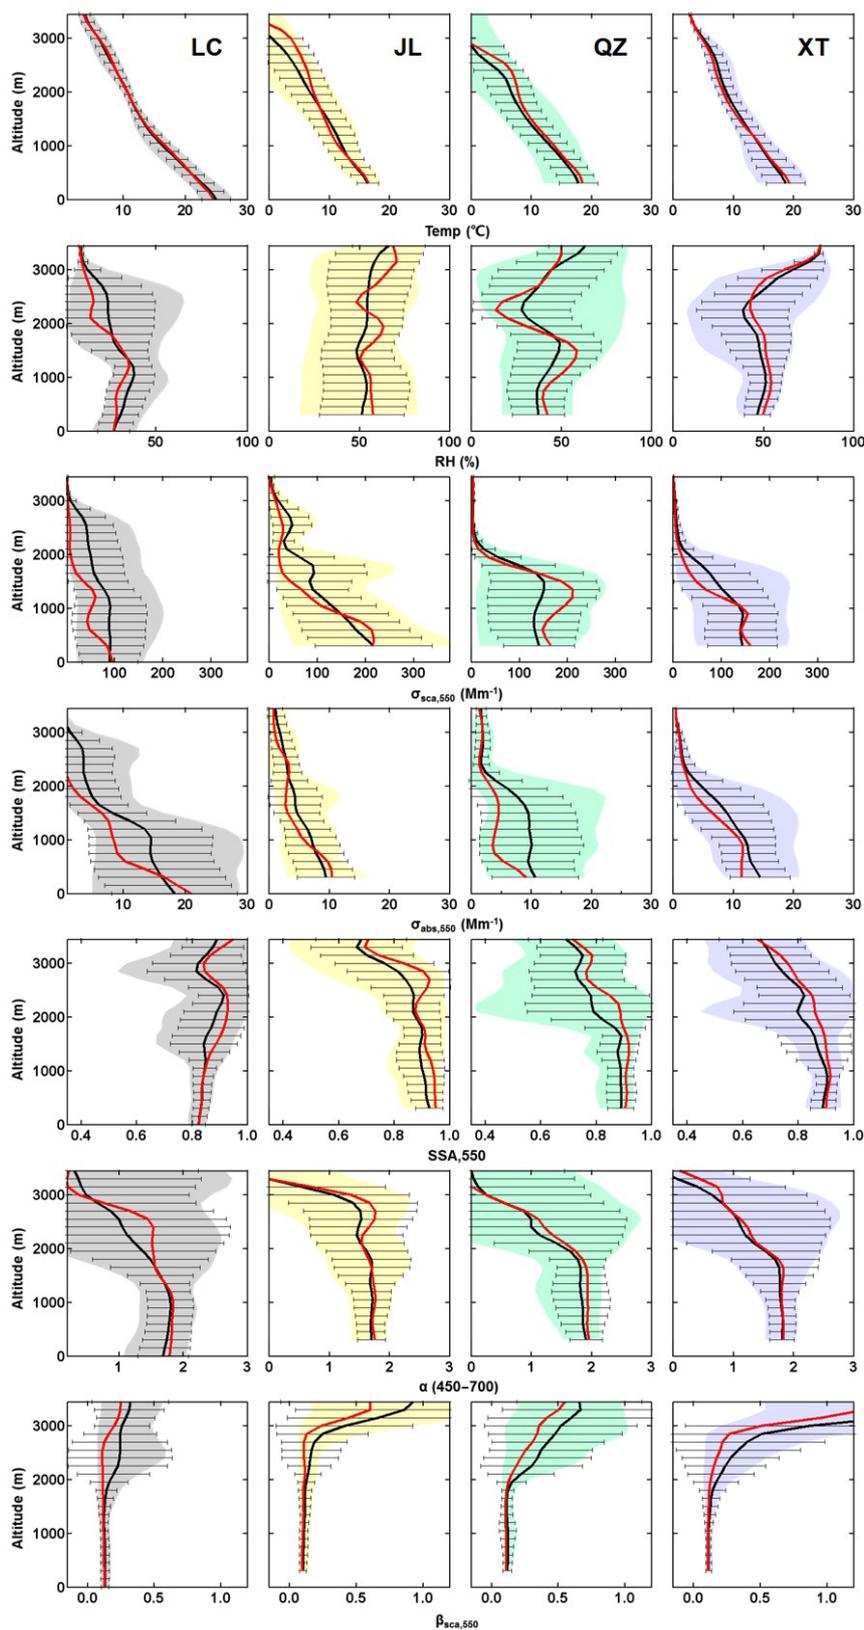

Figure 4. Mean vertical distributions of (from the top row to the bottom row) temperature ($^{\circ}\text{C}$), relative humidity (%), σ_{sca} at 550 nm (Mm^{-1}), σ_{abs} at 550 nm (Mm^{-1}), SSA at 550 nm, Ångström exponent (α), and β_{sca} at 550 nm over LC, JL, QZ, and XT (from the left column to the right column, respectively). Black and red lines represent the mean and the median, respectively, and horizontal bars are standard deviations at every 150 m level. The colored shaded areas represent the 10th and 90th percentiles of the data.

suggest that particle sizes changed quickly, due presumably to different air masses transported from different directions.

During the experiment period, the majority of aerosol layers were well characterized by the sampled vertical profiles, and most aerosols resided below the maximum flight levels. Mie theory was applied to calculate the extinction profiles and the AOD and to estimate the impact of different aerosol vertical distributions on these optical properties. The AOD was calculated by integrating the extinction coefficient over height as

$$\text{AOD}_{(z_1 \sim z_2)} = \int_{z_1}^{z_2} \sigma_{\text{ext}}(z) dz, \quad (7)$$

where $\sigma_{\text{sca}}(z)$ is the extinction coefficient at a height of z and Z_2 is above most of the aerosol. Figure 5 shows the mean AOD at 550 nm for different altitude ranges. The regional mean AOD in each altitude range (< 1, 1–2, and 2–3 km) was 0.10 ± 0.08 , 0.10 ± 0.07 , and 0.03 ± 0.03 , respectively. Standard deviations are greater than 50 % of the mean, suggesting that AODs varied greatly within an altitude range. The magnitude of AOD generally decreased with altitude. The effect of the transport of atmospheric pollutants is evident at QZ, where the largest AOD values were found in the 1–2 km layer instead of at the surface.

4 PBL structure and aerosol σ_{sca} as a function of RH

The vertical distribution of aerosol particles is important for determining radiative effects, especially in the presence of clouds. During haze episodes, the vertical profiles of CO, the aerosol concentration, and the scattering coefficient have been found to be well correlated (Haywood et al., 2003b). Formenti et al. (2003a, b) presented a full analysis of the correlations among these variables. Examples of typical vertical profiles of aerosol scattering and RH, and transport pathways over the target areas are presented here.

4.1 Clean PBL

Generally driven by the weather conditions at flight time, a clean PBL is defined by a mean value of σ_{sca} less than 100 Mm^{-1} in every 100 m layer (except that adjacent to the surface layer). Figure 6a and c show the vertical profiles of σ_{sca} and ambient RH, retrieved from airborne measurements made under clean PBL conditions. Values of σ_{sca} near the surface ranged from 11.7 to 84.5 Mm^{-1} , with an average value of 48.5 Mm^{-1} . In general, σ_{sca} slowly decreased with height, which suggests that the atmosphere was relatively clean, with no distinct aerosol layer identified. The mean σ_{sca} profile decreases approximately exponentially with height, expressed as

$$\sigma_{\text{sca},H} = \quad (8)$$

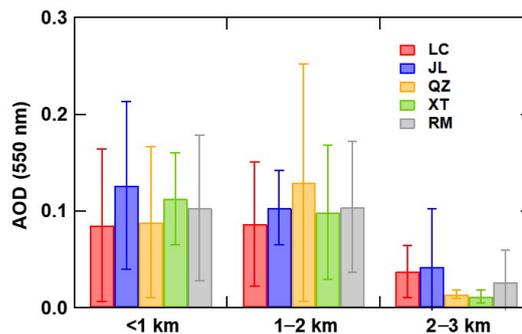

Figure 5. Mean AOD at 550 nm at LC, JL, QZ, and XT, and overall mean AOD (RM) at 550 nm for different altitude ranges (< 1, 1–2, and 2–3 km). Standard deviations are also shown.

$$\begin{cases} \sigma_{\text{sca},0} \cdot \exp(-(H - H_{\text{RS}})/H_p), & (\text{if } H > H_{\text{RS}}) \\ \sigma_{\text{sca},0} & (\text{if } H \leq H_{\text{RS}}) \end{cases},$$

where $\sigma_{\text{sca},0}$ is σ_{sca} measured at the surface, H is the altitude above sea level, and H_p is the aerosol scale height (H_p represents the height where σ_{sca} is reduced to $1/e$ of its surface value); H_{RS} represents a relative stable layer near the surface where the vertical variation of σ_{sca} was insignificant. In the cases of a clean PBL, $\sigma_{\text{sca},0} = 124 \text{ Mm}^{-1}$, $H_p = 1146 \text{ m}$, and $H_{\text{RS}} = 837 \text{ m}$. A linear regression analysis shows the correlation coefficient, $r^2 = 0.96$. The ambient RH under clean PBL conditions was divided into two groups: dry (RH: 27.4–36.8 %) and humid (RH: 53.1–83.6 %). Under dry conditions, σ_{sca} and ambient RH showed a good correlation ($R^2 = 0.62$, Fig. 8a), while under humid conditions, the correlation was low ($R^2 = 0.23$). To understand the sources and transport pathways of aerosols over the target areas during the field campaign, we calculated isentropic air mass back trajectories for 72 h using the NOAA Hybrid Single Particle Lagrangian Integrated Trajectory (HYSPLIT) model (Draxler and Hess, 1997; Stein et al., 2016) at 0.5, 1.5, and 2.5 km above mean sea level. The HYSPLIT model (<http://ready.arl.noaa.gov/HYSPLIT.php>, last access: 6 June 2018) was used along with the National Center for Environmental Prediction's Global Data Assimilation System $1^\circ \times 1^\circ$ meteorological database to calculate backward trajectories terminated at the Xingtai supersite. Figure 9a shows 72 h air mass back trajectories under clean PBL conditions during the field campaign. Air masses most commonly originated from the northwestern region of the study area. Some of the trajectories can be traced back as far as Mongolia and Siberia, passing over the arid areas to the west of southern Hebei. Some clean and moist air masses originating from the less polluted southern and local areas were also seen.

4.2 Pollution in the lower layer of the PBL

The vertical distribution of air pollutants varied greatly from case to case due to a variety of influences. One of the crucial factors was PBL structure, which determines the vertical

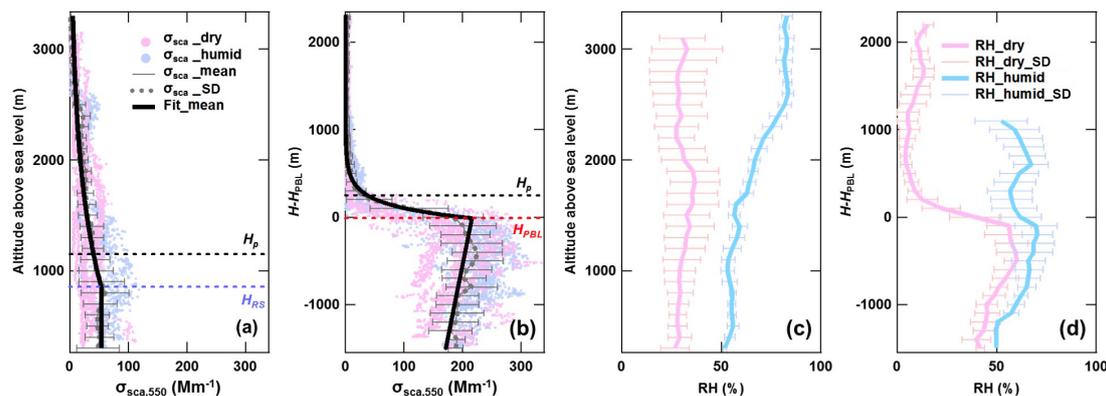

Figure 6. Mean vertical distributions of σ_{sca} at 550 nm (in Mm^{-1}) and relative humidity (%) during the flight campaign for those cases of (a, c) clean PBL and (b, d) pollution in the lower layer of the PBL where PBL heights have been normalized to the same altitude. Grey dashed lines represent mean σ_{sca} vertical profiles, the light pink and blue dots represent 1 s nephelometer-measured σ_{sca} under dry or humid conditions, respectively. Thick lines show the calculated fitting curves of the σ_{sca} profiles (see Eqs. 8 and 9). Magenta and blue lines represent RH data collected under dry or humid conditions (c, d). The horizontal error bars represent the standard deviations at every 100 m level.

profile of σ_{sca} ; see Fig. 6b. The corresponding ambient RH profiles (Fig. 6d), σ_{sca} as a function of RH (Eq. 9), and the back-trajectory analysis (Fig. 9b) are also shown. The PBL height is determined by the shapes of σ_{sca} vertical profiles. When pollution is confined primarily to the lower layer of the troposphere, the magnitude of σ_{sca} increased slightly with height up to an altitude where σ_{sca} decreased sharply. In this study, the mean rate of decrease was about $0.81 \text{ Mm}^{-1} \text{ m}^{-1}$. We defined the bottom of this layer as PBL height (H_{PBL}). We normalized the curves by the shapes of σ_{sca} vertical profiles, and the PBL heights of different σ_{sca} and ambient RH profiles were adjusted to the same level to show the similarity of the shapes. The PBL heights, as determined by vertical profiles of σ_{sca} , ranged from 900 to 2000 m with an average value of ~ 1400 m. The average σ_{sca} profile was determined as follows:

$$\sigma_{\text{sca},H} = \begin{cases} \sigma_{\text{sca},\text{PBL}} \cdot \exp(-(H - H_{\text{PBL}})/H_p), & (\text{if } H > H_{\text{PBL}}) \\ \sigma_{\text{sca},0} + k \cdot H, & (\text{if } H \leq H_{\text{PBL}}) \end{cases}, \quad (9)$$

where H_{PBL} is the normalized altitude of PBL height, H_p is the aerosol scale height in the free troposphere, and k is the changing rate of σ_{sca} in the PBL. In these cases, $\sigma_{\text{sca},0} = 171 \text{ Mm}^{-1}$, $H_p = 216$ m, $k = 0.03 \text{ Mm}^{-1} \text{ m}^{-1}$, and $r^2 = 0.9394$. Figure 6d shows the ambient RH profiles under dry and humid conditions. The shapes of dry and humid RH profiles were similar in the PBL, but at the top of the PBL, the RH_{dry} profiles decreased dramatically, and the RH_{humid} profiles changed only slightly. Linear fits were made to determine the correlation between RH and σ_{sca} . Under dry conditions, there was a pronounced correlation ($r^2 = 0.95$) between RH_{dry} and σ_{sca} profiles. But under humid conditions, the correlation coefficient was only 0.12, suggesting little impact of RH on σ_{sca} .

Most back trajectories under polluted conditions originated from the heavily populated and industrialized interior and coastal areas south of the study area (Fig. 9b). Some drier air masses (corresponding to RH_{dry}) were traced back to southern and local areas just as in the case of clean air masses. Moist air masses originated from the clean marine atmosphere to the southeast, then passed over the densely populated eastern/southeastern regions in the free troposphere before reaching the observation site. This analysis of both dry and moist air masses with aerosols in the lowest layer of the PBL shows that heavy local/regional pollution dominated during the field campaign and that the long-range transport of aerosols was less significant.

4.3 Pollution in the middle and upper layers of the PBL

In addition to high aerosol concentrations in the lower PBL, upper-layer (referred to as the type A case, an example of which occurred on 2 June 2016) and multi-layer (referred to as the type B case, an example of which occurred on 6 June 2016) aerosol vertical distributions were also observed. In the type A case (Fig. 7a), the vertical profile of aerosol σ_{sca} retrieved from airborne measurements shows a mean σ_{sca} near the surface of about 45 Mm^{-1} and little variation below 1 km. A sharp increase in σ_{sca} was observed above with a peak value of 200 Mm^{-1} occurring around 2–3 km, and aloft the σ_{sca} profile decreased exponentially with height. For the type B case (Fig. 7b), mean σ_{sca} varied greatly with height, which suggests that multiple layers of aerosol particles were present in the PBL. The vertically inhomogeneous distribution of σ_{sca} suggests that aerosol particles in the PBL might be significantly affected by the long-range transport of air pollutants or local emissions in the study area. The profiles of σ_{sca} and ambient RH for type A and type B cases have

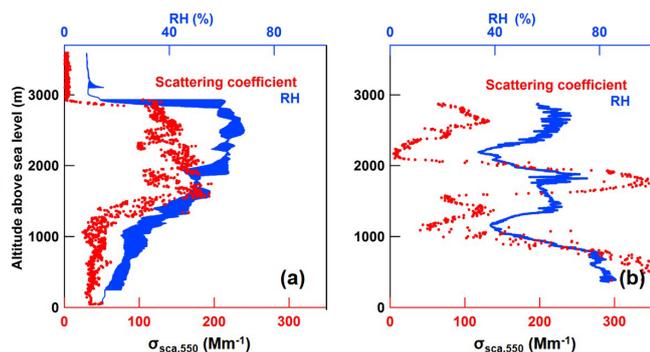

Figure 7. Vertical distributions of σ_{sca} at 550 nm (red) and relative humidity (RH, blue) for the enrichment of aerosols in the upper layer of the PBL on 2 June in LC (a) and in multiple layers of the PBL on 6 June in JL (b).

similar shapes with a correlation coefficient of $R^2 = 0.91$ and 0.59 , respectively (Fig. 8c and d).

As shown in Fig. 9c, back trajectories for the type A case originated from less polluted regions in northeastern China which then moved toward the marine atmosphere over Bohai Bay and the densely populated region east of the study area. The aerosol enrichment in the upper layer of the PBL was probably due to regional transport and mixture of anthropogenic and sea-salt aerosols into the free troposphere. The back trajectories ending at 0.5, 1.5, and 2.5 km over the observation site for the type B case (Fig. 9d) show that air masses originated from the clean marine environment to the southeast, from the polluted environment to the southwest, and from the eastern coastal region. This could explain the strata, i.e., the multi-layered vertical distribution, of aerosols in the PBL.

5 Conclusions

Vertical distributions of aerosol optical properties were characterized using extensive measurements made by airborne and ground-based instruments during a field experiment in May and June of 2016 in the heavily industrialized North China Plain around Xingtai, Hebei Province. During the field campaign, a total of 11 research flights (about 25 flight hours in total) were made as a part of the A²BC and ARIAs experiment. Measurements used in this study include aerosol scattering and backscattering, absorption, extinction, single scattering albedo, Ångström exponent, and AOD. The vertical and regional characteristics of the PBL structure were characterized to better understand their impact on air quality and climate.

Statistical summaries of the vertical distributions of aerosol optical properties focused on four target areas in the NCP region. A total of 38 profiles were compiled and analyzed. Ground-based CAPS and CIMEL retrievals and meteorological soundings were made at the same time as the air-

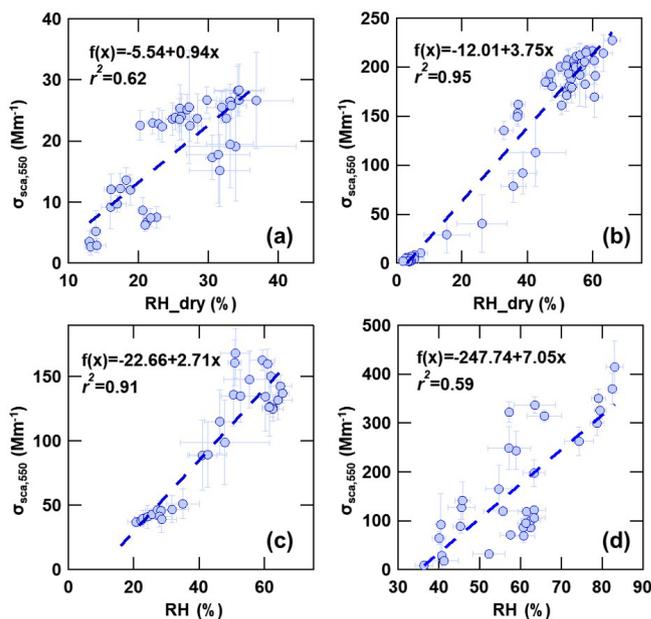

Figure 8. σ_{sca} at 500 nm as a function of relative humidity (RH, in %) for those cases when the PBL was (a) clean and dry, (b) polluted in the lower PBL and dry, (c) polluted in the upper PBL in the flight on 2 June, and (d) polluted in multiple layers of the PBL in the flight on 6 June. The linear regression best-fit lines through the data are shown (dashed lines). The regression relationships and coefficients of determination are given in each panel.

borne measurements to ensure data comparability. Aircraft measurements agree generally well with independent measurements made by radiosondes of temperature and humidity, and with aerosol extinction from CAPS, and aerosol single scattering albedo from the CIMEL sun photometer. While aerosol scattering and extinction coefficients generally decreased with height, there were distinct patterns of profiles for clean and polluted episodes. Profiles over the target area showed relatively high values of σ_{sca} and σ_{abs} , suggesting that there were higher concentrations of light-absorbing and scattering pollutants in this region. Mean SSA (ω_{550}) ranged from 0.83 to 0.87 over the four regions, suggesting that moderately strong-absorbing aerosols are present in the region. The regional mean AOD in each altitude range (<1, 1–2, and 2–3 km) was 0.10 ± 0.08 , 0.10 ± 0.07 , and 0.03 ± 0.03 , respectively. Most of the total aerosol concentration in the lower troposphere was found below 2 km during the aircraft campaign.

Three typical PBL structures were identified, with distinct air mass transport pathways and correlations between σ_{sca} and RH. In the clean PBL, σ_{sca} is strong near the surface and slowly weakens with height. The correlation coefficient of σ_{sca} and ambient RH under relatively dry conditions was 0.62. Clean air masses most commonly originated from the northwest, which is far from the study area.

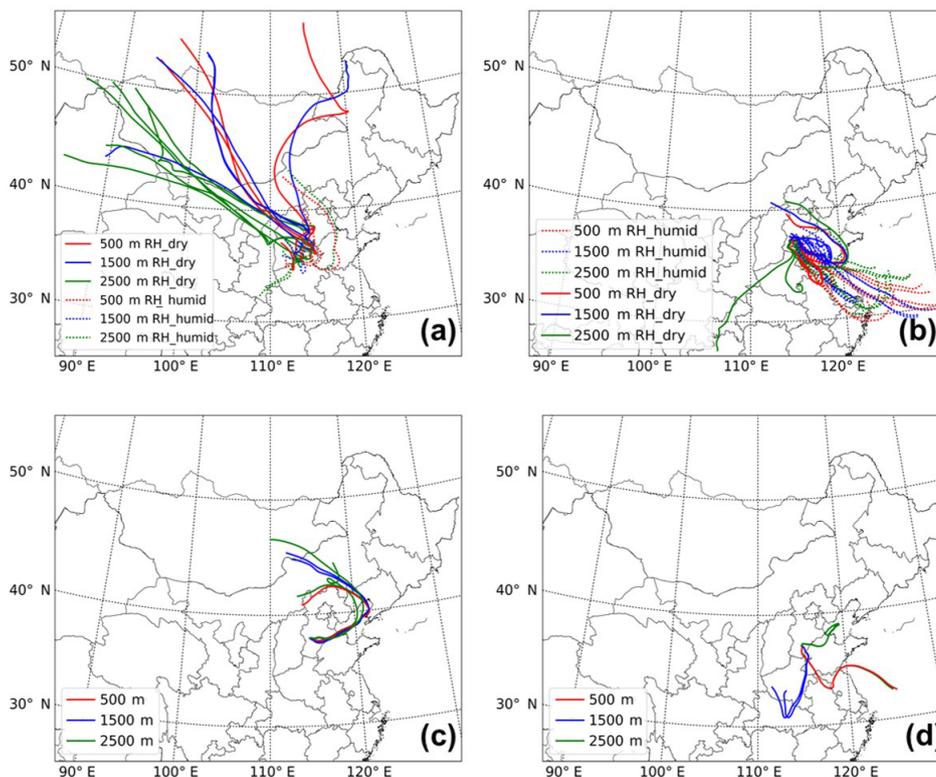

Figure 9. 72 h HYSPLIT back trajectories for the cases when the PBL was (a) clean, (b) polluted in the lower PBL, (c) polluted in the upper PBL in the flight on 2 June, and (d) polluted in multiple layers of the PBL in the flight on 6 June. Trajectories at different levels under dry (solid lines) and humid (dashed lines) conditions are shown: 500 m (red), 1500 m (blue), and 2500 m (green) above mean sea level.

When there was pollution in the lower PBL, σ_{sca} increased slightly with height, then sharply decreased at the top of the PBL. Aerosol scattering and relative humidity showed a good correlation ($R^2 = 0.78$) in the PBL. Most trajectories of this type originated from the heavily polluted interior and coastal areas south and east of the study area. When there was a pollution layer higher in the PBL or multiple layers of pollution, the σ_{sca} and ambient RH profiles had similar shapes, and the PBL structure could be explained by the source and transmission process of air masses.

Data availability. The field experiment data used in this study can be downloaded from <ftp://210.73.20.4> (last access: 12 June 2018). Registration information is available upon request (please contact Fei Wang at feiwang@cma.gov.cn).
